Abstract

Interacting fluids, endowed with bulk viscous stresses, are discussed in a unified perspective with the aim of generalizing the treatment of cosmological perturbation theory to the case where both fluctuating decay rates and fluctuating bulk viscosity coefficients are simultaneously present in the relativistic plasma. A gauge-invariant treatment of the qualitatively new phenomena arising in this context is provided. In a complementary approach, faithful gauge-fixed descriptions of the gravitational and hydrodynamical fluctuations are developed and exploited. To deepen the interplay between bulk viscous stresses and fluctuating decay rates, illustrative examples are proposed and discussed both analytically and numerically. Particular attention is paid to the coupled evolution of curvature and entropy fluctuations when, in the relativistic plasma, at least one of the interacting fluids possesses a fluctuating bulk viscosity coefficient. It is argued that this class of models may be usefully employed as an effective description of the decay of the inflaton as well as of other phenomena involving imperfect relativistic fluids.

1 Formulation of the problem

It is plausible, as observations suggest, that the large-scale temperature fluctuations detected in the microwave sky may arise, via the Sachs–Wolfe effect, from primordial curvature perturbations amplified during the early stages of the life of the Universe. It is therefore mandatory for those interested in this possibility to scrutinize in detail the evolution of curvature fluctuations when the composition of the primeval plasma cannot be parametrized in terms of a single, perfect, relativistic fluid.

A class of dissipative effects that can enter the energy-momentum tensor without spoiling the isotropy of the background geometry can be parametrized in terms of a bulk viscosity coefficient [1] (see also [2]). In fact, in the relativistic theory of imperfect fluids, the dissipative effects can be parametrized in terms of a shear coefficient, a heat flow coefficient and a bulk viscosity coefficient. When written in general coordinates [1] (see also [3]), the contributions of the shear tensor and of the heat flow (unlike the bulk viscosity) do not contribute to a homogeneous and isotropic background geometry of Friedmann-Robertson-Walker type [1].

Following then Ref. [1], for a *single* fluid, the total energy-momentum $\mathcal{T}_\mu^\nu$ tensor can then be split into a perfect contribution, denoted in the following by T_μ^ν , and into an imperfect contribution, denoted by ΔT_μ^ν , i.e.

$$\mathcal{T}_\mu^\nu = T_\mu^\nu + \Delta T_\mu^\nu, \quad (1.1)$$

In general coordinates, and within our set of conventions, the contribution of bulk viscous stresses can be written, in turn, as

$$\Delta T_\mu^\nu = \xi \left(\delta_\mu^\nu - u_\mu u^\nu \right) \nabla_\alpha u^\alpha, \quad (1.2)$$

where ξ represents the bulk viscosity coefficient. The presence of bulk viscosity can also be interpreted, at the level of the background, as an effective redefinition of the enthalpy (i.e. $(\rho + p)$) that appears both in the spatial components of Einstein equations and in the background form of the covariant conservation equation. While this approach may be appropriate at the level of the evolution of the background space-time, it could be confusing if applied to the dynamics of the fluctuations when ξ is allowed to have a spatial dependence.

The presence of bulk viscosity in the relativistic plasma can influence the character of the cosmological singularity [3, 4] (see also [6, 5]). Regular solutions [4] (but generically unstable [3] and probably not past-geodesically complete) can be found if the ξ has some particular functional dependence upon the energy density. Some of these solutions have the property that as $t \rightarrow -\infty$ (t being the cosmic time coordinate) the scale factor approaches a quasi-de

Sitter stage of accelerated expansion. These deflationary solutions [7] violate, initially, the strong energy condition, i.e. $(\rho + 3\mathcal{P}) \geq 0$, where $\mathcal{P} = p - 3H\xi$ is the total pressure and p is the pressure arising from the perfect contribution (i.e. $T_i^j = -p\delta_i^j$) introduced in Eq. (1.1). The dominant energy condition [8] could be violated when bulk viscous stresses are added [7]. This second occurrence implies that the effective enthalpy, i.e. $(\rho + \mathcal{P})$, may not always be positive-definite in all the classes of solutions involving a homogeneous (viscous) background. Boundary conditions can be imposed in such a way that for $t \rightarrow +\infty$ the solution approaches, asymptotically, de Sitter space-time. In the latter case the solutions are driven to an inflationary phase [7].

Barrow [7] presented detailed studies (see also [9, 10]) on inflationary Universes driven by a gas of strings showing that, in some regimes, this system can be discussed in terms of an effective bulk viscosity coefficient. The solutions quoted in the previous paragraphs have been generalized along different lines. In [7] the bulk viscosity coefficient ξ is taken to be proportional to a power of the energy density, i.e. $\xi \propto \rho^m$. The relevance of these examples for the cosmic no-hair theorems has also been investigated in a series of papers [9, 10]. Moreover it was argued that, as one traces the Universe back in time, a point is reached when the expansion rate is so fast that the rate of string creation due to quantum effects balances the dilution of the string density due to the expansion [11]. These considerations lead naturally to an effective bulk viscosity coefficient that may induce an approximate, weak, inflationary dynamics.

The possibility of driving a robust inflationary phase by means of bulk viscous stresses has been indeed criticized on various grounds (see [12, 13, 14]). In [12] it has been argued that the bulk viscosity effects associated with a gas of weakly interacting particles cannot make the pressure negative excluding any form of inflation. In [13] it has been suggested that hydrodynamic inflation is intrinsically problematic (see also [14] for an interesting, related perspective) since while the inflationary evolution requires a very small expansion time the hydrodynamic regime requires a very small interaction time. Therefore, to treat consistently the problem one would need a consistent (non-linear) generalization of the Israel-Stewart transport equations (see the attempt of Ref. [15]) as well as a consistent model of fluid behaviour under super-rapid expansion and strongly non-linear conditions. The possibility of realizing a sufficiently long and robust inflationary phase is, however, not central for the present analysis: in the present context the possible effects of bulk viscosity will arise after the end of a (conventional or unconventional) inflationary phase.

The effect of bulk viscous stresses has also been studied in the case of scalar-tensor theories of gravity (see for instance [16]). More recently, the possible implications of bulk viscosity on the dynamics of the dark energy fluid have been investigated in different frame-

works [17] (see also [18] and references therein). In [17] the hope is to obtain naturally an accelerated expansion from bulk viscous effects.

An apparently unrelated effect is the energy exchange between different fluids whose mixture constitutes the global relativistic plasma that drives the evolution of the geometry. For instance, it is conceivable that, after inflation, the oscillating inflaton field decays into massless particles [19]. Then this situation can be modelled by a fluid of dusty matter decaying into a fluid of radiation. Multifluids also arise in the discussion of isocurvature modes like, for instance, the CDM-radiation isocurvature mode. In all these problems, one of the relevant aspects is the analysis of the evolution of curvature and entropy perturbations.

The theory of cosmological perturbations in the presence of different fluids has a long history. For instance, in [19] the problem of multifluids was analysed in the absence of bulk viscosity. In [22] multifluid systems have been treated in the framework of a covariant cosmological perturbation (see [23] for an introduction and [24] for related applications). Entropy perturbations arising in multifluid systems have also been discussed in [25, 26, 27, 28] in the context of the Bardeen formalism [29], as well as in the context of inflationary models [31, 35] and quintessence models [32, 33, 34, 36]. Possible effects connected with the decay of the inflaton have recently been considered in [37, 38]. Notice finally that earlier works in the general area of bulk viscosity can be found in [39, 40].

It has been argued, in recent years, that interacting (multiple) fluids may play some relevant rôle in cosmological perturbation theory. If the early Universe contains more than a single fluid, the spatial variations of the decay rate may indeed generate curvature perturbations [41] (see also [42] and [43, 44, 45, 46]).

In the present paper a unified description of imperfect fluids is developed with the aim of understanding if and how the effect of spatial fluctuations in the bulk viscosity coefficient (combined with a non-vanishing decay rate) may induce super-horizon curvature perturbations. In this sense, we are not interested in discussing the evolution of the fluctuations in the case when a *single* viscous fluid is present. Let us phrase the problem in physical terms. Consider the situation where the matter content of the Universe is formed by, at least, *two fluids*. The possible dissipative effects compatible with the isotropy of the background geometry are:

- energy exchange between the fluids;
- bulk viscous effects associated with each fluid and with the mixture.

The first type of effect can be parametrized by a (time-dependent) decay rate that is allowed to fluctuate spatially. These fluctuations may then induce fluctuations on super-

horizon scales (see, again, [41, 42, 43, 44, 45, 46]). The second type of effects can be parametrized by the appropriate second viscosity coefficients of each fluid of the mixture and by their related fluctuations. Also in this case it is reasonable to expect that the fluctuations of the second viscosity coefficient can be converted into super-horizon curvature fluctuations. There may be, in principle, two extreme situations. In one case the presence of bulk viscous stresses crucially determines the nature of the background geometry. This is the approach studied, for instance, in [4, 7, 11, 16]. In the other situation, the bulk viscosity does not determine crucially the properties of the background geometry. This approach is hard to justify for a single (non decaying) viscous fluid, but it becomes plausible when there are at least two interacting fluids. Consider, for instance, the situation where the fluid describing the decay products has no intrinsic viscosity, while the fluid that is effectively decaying has some intrinsic viscosity. If, as in [7], ξ depends on the energy density of the decaying fluid, it is reasonable to expect that when the decay is completed, the bulk viscous effects will also decay. Depending on the specific parameters of the example, it is then conceivable that, the net result of the evolution will be a single inviscid fluid supplemented by an exponentially decaying (viscous) component with negligible effect on the dynamics of the background. It is interesting to understand what happens to the dynamics of the fluctuation. If the decaying fluid has some intrinsic viscosity, the effect on the curvature fluctuations may be relevant even if, when the decay is completed, the viscous contribution goes exponentially to zero at a rate that depends upon the relative interaction of the fluids of the mixture.

From a more formal point of view, one of the problems is a full gauge-invariant treatment of imperfect cosmological perturbations where the fluctuations of both the bulk viscosity coefficient and the decay rate are invariant under infinitesimal diffeomorphisms. The gauge-invariant approach will be complemented with gauge-fixed descriptions that are particularly useful in connection with the intricacy of the numerical calculations.

The present article is organized as follows. In Section 2 the basic framework of the analysis will be illustrated. Section 3 contains the gauge-invariant description of cosmological perturbations in the presence both of a fluctuating decay rate and of a fluctuating bulk viscosity coefficient. In Section 4 the gauge-invariant evolution equations for the curvature perturbations will be introduced, while in Section 5 curvature perturbations will be discussed in the context of a gauge-fixed description. Section 6 contains various numerical examples clarifying the interplay between fluctuating bulk viscosity and fluctuating decay rate. Finally, Section 7 contains the summary of the main findings and the concluding discussions. For completeness, the analysis of the evolution of the vector modes has been included in an appendix.

2 Basic considerations

Some physical quantities relevant to the problem at hand will now be introduced. As already pointed out, there are two independent physical effects that may compete in a mixture of relativistic fluids: the presence of a (fluctuating) decay rate and the presence of a (fluctuating) bulk viscosity coefficient.

Consider a relativistic plasma formed by, at least, two species. The associated energy-momentum tensors can be written as ²

$$\begin{aligned} T_a^{\mu\nu} &= (p_a + \rho_a) u_a^\mu u_a^\nu - p_a g^{\mu\nu}, \\ T_b^{\mu\nu} &= (p_b + \rho_b) u_b^\mu u_b^\nu - p_b g^{\mu\nu}. \end{aligned} \quad (2.1)$$

If the fluids are decaying one into one another (for instance the a-fluid decays into the b-fluid), the covariant conservation equation only applies to the global relativistic plasma, while the energy-momentum tensors of the single species are not covariantly conserved and their specific form accounts for the transfer of energy between the a-fluid and the b-fluid:

$$\begin{aligned} \nabla_\mu T_a^{\mu\nu} &= -\Gamma g^{\nu\alpha} u_\alpha (p_a + \rho_a), \\ \nabla_\mu T_b^{\mu\nu} &= \Gamma g^{\nu\alpha} u_\alpha (p_a + \rho_a), \end{aligned} \quad (2.2)$$

where the term Γ is the decay rate that can be both space- and time-dependent; in Eqs. (2.2) u_α represents the (total) peculiar velocity field. Owing to the form of Eqs. (2.2), it is clear that the total energy-momentum tensor of the two fluids, i.e. $T_{\text{tot}}^{\mu\nu} = T_a^{\mu\nu} + T_b^{\mu\nu}$ is indeed covariantly conserved.

Equations (2.2) can be easily generalized to the description of more complicated dynamical frameworks, where the relativistic mixture is characterized by more than two fluids. Consider the situation where the a-fluid decays as $a \rightarrow b + c$. Then, if a fraction f of the a-fluid decays into the b-fluid and a fraction $(1 - f)$ into the c-fluid, Eqs. (2.2) can be generalized as

$$\begin{aligned} \nabla_\mu T_a^{\mu\nu} &= -\Gamma g^{\nu\alpha} u_\alpha (p_a + \rho_a), \\ \nabla_\mu T_b^{\mu\nu} &= f \Gamma g^{\nu\alpha} u_\alpha (p_a + \rho_a), \\ \nabla_\mu T_c^{\mu\nu} &= (1 - f) \Gamma g^{\nu\alpha} u_\alpha (p_a + \rho_a), \end{aligned} \quad (2.3)$$

and so on.

²The signature of the four-dimensional metric adopted here is mostly minus, i.e. $(+, -, -, -)$. Latin subscripts are used to distinguish the pressures and energy densities of different fluids; tensor indices are instead denoted by lowercase Greek letters.

It is appropriate to recall here that the authors of Ref. [19] choose to parametrize the coupling between the fluids of the mixture through a more generic function. For instance, in the notations of [19], the source terms of Eqs. (2.2) will simply be Q_a^ν and Q_b^ν bound by the condition³ $Q_a^\nu + Q_b^\nu = 0$. The latter condition follows from the covariant conservation of the total energy-momentum tensor of the mixture and it is also satisfied by the source terms in Eq. (2.2). The second condition satisfied by the source terms is that their spatial component has to be zero when evaluated on the Friedmann-Robertson-Walker background. In the present approach, the spatial part of the source terms given in Eq. (2.2) automatically vanish on the Friedmann-Robertson-Walker background since $g^{\mu\nu}\bar{u}_\mu\bar{u}_\nu = 1$ (implying $\bar{u}_0 = 1$ and $\bar{u}_i = 0$).

The second relevant dissipative effect that can enter the energy-momentum tensor without spoiling the isotropy of the background geometry, as discussed in the previous section, is the one parametrized in terms of bulk viscosity. Following the notation of Eqs. (1.1) and (1.2), the effective energy-momentum tensors of the two fluids can be written as

$$\begin{aligned}\mathcal{T}_a^{\mu\nu} &= T_a^{\mu\nu} + \Delta T_a^{\mu\nu}, \\ \mathcal{T}_b^{\mu\nu} &= T_b^{\mu\nu} + \Delta T_b^{\mu\nu}.\end{aligned}\tag{2.4}$$

Hence, the Einstein equations can be written as

$$R_\mu^\nu - \frac{1}{2}\delta_\mu^\nu R = 8\pi G T_\mu^\nu,\tag{2.5}$$

where,

$$\mathcal{T}^{\mu\nu} = \mathcal{T}_a^{\mu\nu} + \mathcal{T}_b^{\mu\nu}.\tag{2.6}$$

According to Eqs. (1.1),(1.2) and (2.1), $\mathcal{T}_a^{\mu\nu}$ and $\mathcal{T}_b^{\mu\nu}$ will have an inviscid background value (characterized by $p_{a,b}$ and $\rho_{a,b}$) and a viscous correction parametrized, at the level of the background, by $\bar{\xi}_a$ and $\bar{\xi}_b$.

In the following the background geometry will be taken to be of Friedmann-Robertson-Walker (FRW) type. Moreover, it will be assumed that the background geometry is spatially flat so that the line element can be written as

$$ds^2 = dt^2 - a^2(t)d\vec{x}^2,\tag{2.7}$$

where t is the cosmic time coordinate. Therefore, Eq. (2.5) implies⁴

$$H^2 = \frac{8\pi G}{3}\rho,\tag{2.8}$$

$$\dot{H} = -4\pi G(\rho + \mathcal{P}),\tag{2.9}$$

³See, for instance, Eqs. (5.1), (5.2) and (5.3) of [19], page 28.

⁴We denote by an overdot a derivation with respect to the cosmic time-coordinate t .

where $H = \dot{a}/a$ is the Hubble rate; $\rho = \rho_a + \rho_b$ and $p = p_a + p_b$ denote the total (inviscid) energy and pressure densities while $\mathcal{P}$ is the effective total pressure containing the viscous contribution, i.e.

$$\mathcal{P} = p - 3\bar{\xi} H \equiv (p_a + p_b) - 3(\bar{\xi}_a + \bar{\xi}_b) H. \quad (2.10)$$

In the following sections, the total background viscosity coefficient will be denoted by $\bar{\xi}$, i.e.

$$\bar{\xi} = \bar{\xi}_a + \bar{\xi}_b + \dots, \quad (2.11)$$

where the ellipses stand for the possible contribution of other fluids. The definitions of the effective pressures for each fluid follows from Eq. (2.10) and it is

$$\mathcal{P}_a = p_a - 3\bar{\xi}_a H, \quad \mathcal{P}_b = p_b - 3\bar{\xi}_b H. \quad (2.12)$$

Notice, furthermore, that $\bar{\xi}$ (and, similarly $\bar{\xi}_a$ and $\bar{\xi}_b$) denotes the background values of the bulk viscosity coefficients. In different physical examples (see e.g. [4, 7] and also [11]) the bulk viscosity coefficient is proportional to a power of the energy density. If the a- and b-fluids would not be allowed to exchange energy and momentum, the mixture could be described by a single total fluid with effective pressure $\mathcal{P}$. If the decay rate does not vanish, Eqs. (2.2) must be generalized so as to include both decay rate and viscous contribution:

$$\nabla_\mu \mathcal{T}_a^{\mu\nu} = -\Gamma g^{\nu\alpha} u_\alpha (p_a + \rho_a), \quad (2.13)$$

$$\nabla_\mu \mathcal{T}_b^{\mu\nu} = \Gamma g^{\nu\alpha} u_\alpha (p_b + \rho_b). \quad (2.14)$$

In the case of a spatially flat FRW background, denoting with $\bar{\Gamma}$ the homogeneous component of the decay rate, Eqs. (2.13) and (2.14) reduce to

$$\dot{\rho}_a + 3H(\rho_a + \mathcal{P}_a) + \bar{\Gamma}(\rho_a + p_a) = 0 \quad (2.15)$$

$$\dot{\rho}_b + 3H(\rho_b + \mathcal{P}_b) - \bar{\Gamma}(\rho_a + p_a) = 0. \quad (2.16)$$

Notice, once more, the difference between the effective pressures (i.e. $\mathcal{P}_a$ and $\mathcal{P}_b$ defined in Eq. (2.12)) and the inviscid pressures (i.e. p_a and p_b).

In the following sections we are going to study the evolution of the inhomogeneities in the class of background models introduced in the present section. Therefore, while the background quantities will be only function of the time coordinate, the fluctuations will be functions of both time and space.

In the present paper the bulk viscous effects will be parametrized in the context of the Eckart approach [47] (which is the one also followed in [1]). It must be mentioned, that this approach is phenomenological in the sense that the bulk viscosity is not modeled on the basis of a suitable microscopic theory. For caveats concerning the Eckart approach see

[48] (see also [13] and references therein). This Eckart approach, however, fits with the phenomenological inclusion of a fluid decay rate that has been also considered recently for related applications to cosmological perturbation theory. Possible generalizations of the considerations reported in this paper to causal thermodynamics will not be examined here (see [40] for a covariant approach to this problem).

3 Cosmological perturbations for imperfect fluids

As is well known [29], density and metric perturbations may obey formally different evolution equations, depending upon the specific gauge used to perform a given calculation. Once a specific gauge-invariant quantity is computed in a given gauge, it will be, by definition, the same in all the other coordinate systems. Not all coordinate systems are equivalent for specific applications, since one particular gauge may turn out to be more convenient for practical reasons.

In the following the evolution equations of the fluctuations will be derived without choosing a specific gauge. This strategy has a twofold advantage. Firstly the full gauge-invariant evolution equations can be swiftly derived. Secondly, the most useful gauge choices can be selected by comparing the different forms of the equations in different coordinate systems. To begin with, the scalar modes of the Einstein equations will be first derived. We will then move to the evolution equations of the hydrodynamical quantities, i.e. the pressure and density fluctuations and the peculiar velocity of each fluid. While in the present and in the following sections the attention will be focused on the scalar modes of the geometry, some considerations on the evolution of the vector modes are collected in the appendix.

3.1 Einstein system

The scalar perturbation of Einstein equations can be formally written as

$$\delta_s \mathcal{G}_\mu^\nu = 8\pi G \delta_s T_\mu^\nu, \quad (3.1)$$

where δ_s denotes the first-order scalar fluctuation of a given quantity and where $\mathcal{G}_\mu^\nu$ denotes the Einstein tensor. Recalling Eq. (1.1) the scalar fluctuation of the effective energy-momentum tensor of the fluid sources then becomes, in general coordinates

$$\begin{aligned} \delta_s T_\mu^\nu &= \bar{u}_\mu \bar{u}^\nu [(\delta p + \delta \rho) - \delta \xi \bar{\nabla}_\lambda \bar{u}^\lambda - \bar{\xi} \delta(\nabla_\lambda u^\lambda)] \\ &+ \delta_\mu^\nu [\delta \xi \bar{\nabla}_\lambda \bar{u}^\lambda - \delta p + \bar{\xi} \delta(\nabla_\lambda u^\lambda)] \\ &+ (\delta u_\mu \bar{u}^\nu + \bar{u}_\mu \delta u^\nu) [(p + \rho) - \bar{\xi} \bar{\nabla}_\lambda \bar{u}^\lambda], \end{aligned} \quad (3.2)$$

where the (total) velocity field satisfies $g^{\mu\nu}u_\mu u_\nu = 1$ and where the bar means that the corresponding quantity has to be evaluated using the background geometry. To write Eq. (3.2) in explicit terms one has to make explicit the first-order fluctuation of the covariant derivative of the velocity field, i.e. $\delta(\nabla_\lambda u^\lambda)$. Recalling, in fact, that $\nabla_\lambda u^\lambda = \partial_\lambda u^\lambda + \Gamma_{\beta\alpha}^\lambda u^\alpha$ we have that

$$\delta(\nabla_\lambda u^\lambda) = \partial_\lambda \delta u^\lambda + \delta\Gamma_{\alpha\beta}^\lambda \bar{u}^\alpha + \bar{\Gamma}_{\alpha\beta}^\lambda \delta u^\alpha, \quad (3.3)$$

where $\bar{\Gamma}_{\beta\alpha}^\beta$ and $\delta\Gamma_{\beta\alpha}^\beta$ are, respectively, the background and the perturbed Christoffel connections.

Without performing any gauge choice, the scalar fluctuations of a conformally flat metric with line element

$$ds^2 = \bar{g}_{\mu\nu} dx^\mu dx^\nu \equiv a^2(\tau)[d\tau^2 - d\vec{x}^2], \quad (3.4)$$

are parametrized by four independent functions so that the entries of the perturbed metric can be written as

$$\begin{aligned} \delta_s g_{00} &= 2a^2 \phi, & \delta_s g^{00} &= -\frac{2}{a^2} \phi \\ \delta_s g_{ij} &= 2a^2(\psi \delta_{ij} - \partial_i \partial_j E), & \delta_s g^{ij} &= -\frac{2}{a^2}(\psi \delta^{ij} - \partial^i \partial^j E), \\ \delta_s g_{0i} &= -a^2 \partial_i B, & \delta_s g^{0i} &= -\frac{1}{a^2} \partial^i B; \end{aligned} \quad (3.5)$$

note that δ_{ij} is nothing but the Kronecker's delta.

In Eq. (3.5) the conformal time parametrization of the background geometry has been assumed and the evolution equations of the background can be written as ⁵

$$\mathcal{H}^2 = \frac{8\pi G}{3} a^2 \rho, \quad (3.6)$$

$$\mathcal{H}^2 - \mathcal{H}' = 4\pi G a^2 (\rho + \mathcal{P}), \quad (3.7)$$

$$\rho'_a + 3\mathcal{H}(\rho_a + \mathcal{P}_a) + a\bar{\Gamma}(\rho_a + p_a) = 0, \quad (3.8)$$

$$\rho'_b + 3\mathcal{H}(\rho_b + \mathcal{P}_b) - a\bar{\Gamma}(\rho_a + p_a) = 0, \quad (3.9)$$

where $\mathcal{H} = a'/a$. In Eqs. (3.7)–(3.9) the definition of the total and partial shifted pressures follows from Eqs. (2.10) and (2.12). Since $g^{\mu\nu}u_\mu u_\nu = 1$, it also follows, from Eqs. (3.4) and (3.5) that

$$\bar{u}_0 = a, \quad \delta u^0 = -\phi/a. \quad (3.10)$$

Equations (3.3) and (3.5) lead to the following explicit expressions of the fluctuations of the effective energy-momentum tensor

$$\delta \mathcal{T}_0^0 = \delta \rho, \quad (3.11)$$

⁵We denote by a prime a derivation with respect to the conformal time coordinate τ .

$$\delta T_0^i = \left(\rho + p - 3\frac{\bar{\xi}}{a}\mathcal{H} \right) v^i, \quad (3.12)$$

$$\delta T_i^j = -\delta_i^j \left\{ \delta p - 3\frac{\mathcal{H}}{a}\delta\xi - \frac{\bar{\xi}}{a}[\theta - 3(\psi' + \mathcal{H}\phi) + \nabla^2 E'] \right\}, \quad (3.13)$$

where the following notation for the peculiar velocity field and for its divergence has been chosen:

$$u_0 \delta u^i = v^i, \quad \partial_i v^i = \theta. \quad (3.14)$$

Since no specific gauge fixing has been invoked in Eqs. (3.11)–(3.13), Eq. (3.1) allows the determination of the Hamiltonian constraint

$$\nabla^2 \psi - \mathcal{H} \nabla^2 (B - E') - 3\mathcal{H}(\psi' + \mathcal{H}\phi) = 4\pi G a^2 \delta\rho, \quad (3.15)$$

and the momentum constraint

$$\nabla^2 (\psi' + \mathcal{H}\phi) + (\mathcal{H}^2 - \mathcal{H}')(\nabla^2 B + \theta) = 0. \quad (3.16)$$

In the perturbed geometry (3.5), the $(i = j)$ and $(i \neq j)$ components of Eq. (3.1) become, respectively

$$\begin{aligned} & \psi'' + (\mathcal{H}^2 + 2\mathcal{H}')\phi + \mathcal{H}(\phi' + 2\psi') + \frac{1}{2}\nabla^2[(\phi - \psi) + (B - E')' + 2\mathcal{H}(B - E')] \\ &= 4\pi G a^2 \left\{ \delta p - 3\frac{\mathcal{H}}{a}\delta\xi - \frac{\bar{\xi}}{a}[\theta - 3(\psi' + \mathcal{H}\phi) + \nabla^2 E'] \right\}, \end{aligned} \quad (3.17)$$

$$-\frac{1}{a^2}\partial_i \partial^j [(E' - B)' + 2\mathcal{H}(E' - B) + (\psi - \phi)] = 0. \quad (3.18)$$

In Eq. (3.18) the possible contribution of the anisotropic stress has been neglected.

For infinitesimal coordinate transformations, the fluctuations of both the metric and the effective energy-momentum tensor change. Hence, it is always convenient to define appropriate gauge-invariant quantities. A possible set of gauge-invariant quantities is then

$$\Phi = \phi + (B - E')' + \mathcal{H}(B - E') \quad (3.19)$$

$$\Psi = \psi - \mathcal{H}(B - E') \quad (3.20)$$

for the metric and

$$\delta\rho_g = \delta\rho + \rho'(B - E') \quad (3.21)$$

$$\delta p_g = \delta p + p'(B - E') \quad (3.22)$$

$$\Theta = \theta + \nabla^2 E' \quad (3.23)$$

for the (total) fluid sources. In Eqs. (3.21) and (3.22) the subscript “g” means that the corresponding quantity is invariant under infinitesimal coordinate transformations, i.e., for

short, gauge-invariant. This notation will also be employed, when needed, in the following sections. Equations (3.19) and (3.20) are the gauge-invariant fluctuations of the metric sometimes called Bardeen potentials [29]. From Eqs. (3.19) and (3.20), it is clear that in the gauge $E = 0$ and $B = 0$ Φ and Ψ coincide with the longitudinal fluctuations of the metric, i.e. ϕ and ψ [30].

Since the bulk viscosity coefficient is general time dependent, its gauge-invariant fluctuation is defined as

$$\Xi = \delta\xi + \bar{\xi}'(B - E'). \quad (3.24)$$

Following the usual procedure, the various fluctuations both of the geometry and of the sources, i.e. ψ , ϕ , $\delta\rho$, $\delta\xi$ and so on, can be expressed in terms of their gauge-invariant counterparts, i.e. Ψ , Φ , $\delta\rho_g$, Ξ and so on. These expressions can then be inserted into Eqs. (3.15), (3.16) and (3.17), (3.18). The resulting set of equations will now contain only gauge-invariant quantities. The full system will then be formed by the gauge-invariant counterpart of Eqs. (3.15) and (3.16):

$$\nabla^2\Psi - 3\mathcal{H}(\Psi' + \mathcal{H}\Phi) = 4\pi G a^2 \delta\rho_g, \quad (3.25)$$

$$\nabla^2(\Psi' + \mathcal{H}\Phi) + (\mathcal{H}^2 - \mathcal{H}')\Theta = 0, \quad (3.26)$$

and by the gauge-invariant counterpart of Eq. (3.17):

$$\Psi'' + \mathcal{H}(\Phi' + 2\Psi') + (\mathcal{H}^2 + 2\mathcal{H}')\Phi = 4\pi G a^2 \left\{ \delta p_g - \frac{3\mathcal{H}}{a}\Xi - \frac{\bar{\xi}}{a}[\Theta - 3(\Psi' + \mathcal{H}\Phi)] \right\}. \quad (3.27)$$

Equation (3.18) implies that $\Phi = \Psi$ in the absence of anisotropic stress.

3.2 Interacting viscous mixtures

The perturbed form of the covariant conservation equations can be written as

$$\begin{aligned} \delta(\nabla_\mu \mathcal{T}_{(a)}^{\mu\nu}) &= -[\delta\Gamma \bar{g}^{\nu\alpha} \bar{u}_\alpha (p_a + \rho_a) + \bar{\Gamma} \delta g^{\nu\alpha} \bar{u}_\alpha (p_a + \rho_a) \\ &+ \bar{\Gamma} \bar{g}^{\nu\alpha} \delta u_\alpha (p_a + \rho_a) + \bar{\Gamma} \bar{g}^{\nu\alpha} \bar{u}_\alpha (\delta p_a + \delta \rho_a)], \end{aligned} \quad (3.28)$$

$$\begin{aligned} \delta(\nabla_\mu \mathcal{T}_{(b)}^{\mu\nu}) &= [\delta\Gamma \bar{g}^{\nu\alpha} \bar{u}_\alpha (p_a + \rho_a) + \bar{\Gamma} \delta g^{\nu\alpha} \bar{u}_\alpha (p_a + \rho_a) \\ &+ \bar{\Gamma} \bar{g}^{\nu\alpha} \delta u_\alpha (p_a + \rho_a) + \bar{\Gamma} \bar{g}^{\nu\alpha} \bar{u}_\alpha (\delta p_a + \delta \rho_a)]. \end{aligned} \quad (3.29)$$

In [19] the authors choose to parametrize the rate of momentum transfer (in the perturbation equations) through a more generic functions whose properties follow, in the present approach, from the form of the coupling already discussed after Eqs. (2.2) (see, for instance, Eq. (5.18) of [19]).

From Eq. (3.28), without fixing the gauge, we obtain the following general expression from the (0) component

$$\begin{aligned}
& \delta\rho'_a + 3\mathcal{H}(\delta\rho_a + \delta p_a) - 9\frac{\mathcal{H}^2}{a}\delta\xi_a + (\rho_a + \mathcal{P}_a)\theta_a - 3(\rho_a + \mathcal{P}_a)\psi' \\
& - 3\frac{\bar{\xi}_a}{a}\mathcal{H}[\theta_a - 3(\psi' + \mathcal{H}\phi) + \nabla^2 E'] + (\rho_a + \mathcal{P}_a)\nabla^2 E' \\
& = -a[\delta\Gamma(\rho_a + p_a) + \phi\bar{\Gamma}(\rho_a + p_a) + \bar{\Gamma}(\delta\rho_a + \delta p_a)],
\end{aligned} \tag{3.30}$$

while from Eq. (3.29), still for the (0) component, the result will be

$$\begin{aligned}
& \delta\rho'_b + 3\mathcal{H}(\delta\rho_b + \delta p_b) - 9\frac{\mathcal{H}^2}{a}\delta\xi_b + (\rho_b + \mathcal{P}_b)\theta_b - 3(\rho_b + \mathcal{P}_b)\psi' \\
& - 3\frac{\bar{\xi}_b}{a}\mathcal{H}[\theta_b - 3(\psi' + \mathcal{H}\phi) + \nabla^2 E'] + (\rho_b + \mathcal{P}_b)\nabla^2 E' \\
& = a[\delta\Gamma(\rho_a + p_a) + \phi\bar{\Gamma}(\rho_a + p_a) + \bar{\Gamma}(\delta\rho_a + \delta p_a)].
\end{aligned} \tag{3.31}$$

To derive Eqs. (3.30) and (3.31) from Eqs. (3.28) and (3.29), Eqs. (3.8) and (3.9) have been repeatedly used.

The (i) component of Eqs. (3.28) and (3.29) leads, respectively, to the evolution of the peculiar velocity of the a-fluid:

$$\begin{aligned}
& \theta'_a + \left[4\mathcal{H} + \frac{\rho'_a + \mathcal{P}'_a}{\rho_a + \mathcal{P}_a}\right]\theta_a + \nabla^2(B' + \phi) + \left[\mathcal{H} + \frac{\mathcal{P}'_a}{\rho_a + \mathcal{P}_a}\right]\nabla^2 B + \frac{\nabla^2 \delta p_a}{\rho_a + \mathcal{P}_a} \\
& - \frac{3\mathcal{H}\nabla^2 \delta\xi_a}{a(\rho_a + \mathcal{P}_a)} - \frac{\bar{\xi}_a[\nabla^2 \theta_a - 3\nabla^2(\psi' + \mathcal{H}\phi) + \nabla^4 E']}{a(\rho_a + \mathcal{P}_a)} = -a\bar{\Gamma}\frac{\rho_a + p_a}{\rho_a + \mathcal{P}_a}\theta,
\end{aligned} \tag{3.32}$$

and to the evolution of the peculiar velocity of the b-fluid:

$$\begin{aligned}
& \theta'_b + \left[4\mathcal{H} + \frac{\rho'_b + \mathcal{P}'_b}{\rho_b + \mathcal{P}_b}\right]\theta_b + \nabla^2(B' + \phi) + \left[\mathcal{H} + \frac{\mathcal{P}'_b}{\rho_b + \mathcal{P}_b}\right]\nabla^2 B + \frac{\nabla^2 \delta p_b}{\rho_b + \mathcal{P}_b} \\
& - \frac{3\mathcal{H}\nabla^2 \delta\xi_b}{a(\rho_b + \mathcal{P}_b)} - \frac{\bar{\xi}_b[\nabla^2 \theta_b - 3\nabla^2(\psi' + \mathcal{H}\phi) + \nabla^4 E']}{a(\rho_b + \mathcal{P}_b)} = a\bar{\Gamma}\frac{\rho_a + p_a}{\rho_b + \mathcal{P}_b}\theta.
\end{aligned} \tag{3.33}$$

Equations (3.30), (3.31) and (3.32), (3.33) can easily be written only in terms of quantities that are explicitly gauge-invariant. To this purpose it is useful to point out that the gauge-invariant fluctuations related to the bulk viscosity coefficients and to the decay rate can be written as

$$\Xi_{(a,b)} = \delta\xi_{(a,b)} + \bar{\xi}'_{(a,b)}(B - E'), \tag{3.34}$$

$$\delta\Gamma_g = \delta\Gamma + \bar{\Gamma}'(B - E'), \tag{3.35}$$

where the subscripts in Eq. (3.34) imply that the gauge-invariant fluctuation has the same form for both the a- and the b-fluid.

Using Eqs. (3.34) and (3.35), Eqs. (3.30), (3.31) and (3.32), (3.33) can be written in fully gauge-invariant terms. More specifically, Eqs. (3.30) and (3.31) lead, respectively, to

$$\begin{aligned} & \delta\rho'_{\text{g a}} + 3\mathcal{H}(\delta\rho_{\text{g a}} + \delta p_{\text{g a}}) - 9\frac{\mathcal{H}^2}{a}\Xi_{\text{a}} + (\rho_{\text{a}} + \mathcal{P}_{\text{a}})\Theta_{\text{a}} - 3(\rho_{\text{a}} + \mathcal{P}_{\text{a}})\Psi' \\ & - \frac{3}{a}\mathcal{H}\bar{\xi}_{\text{a}}[\Theta_{\text{a}} - 3(\Psi' + \mathcal{H}\Phi)] = \\ & -a[\delta\Gamma_{\text{g}}(\rho_{\text{a}} + p_{\text{a}}) + \bar{\Gamma}(\delta\rho_{\text{g a}} + \delta p_{\text{g a}}) + \bar{\Gamma}(p_{\text{a}} + \rho_{\text{a}})\Phi] \end{aligned} \quad (3.36)$$

and to

$$\begin{aligned} & \delta\rho'_{\text{g b}} + 3\mathcal{H}(\delta\rho_{\text{g b}} + \delta p_{\text{g b}}) - 9\frac{\mathcal{H}^2}{a}\Xi_{\text{b}} + (\rho_{\text{b}} + \mathcal{P}_{\text{b}})\Theta_{\text{b}} - 3(\rho_{\text{b}} + \mathcal{P}_{\text{b}})\Psi' \\ & - \frac{3}{a}\mathcal{H}\bar{\xi}_{\text{b}}[\Theta_{\text{b}} - 3(\Psi' + \mathcal{H}\Phi)] = \\ & a[\delta\Gamma_{\text{g}}(\rho_{\text{a}} + p_{\text{a}}) + \bar{\Gamma}(\delta\rho_{\text{g a}} + \delta p_{\text{g a}}) + \bar{\Gamma}(p_{\text{a}} + \rho_{\text{a}})\Phi], \end{aligned} \quad (3.37)$$

while Eqs. (3.32) and (3.33) become

$$\begin{aligned} & \Theta'_{\text{a}} + \left[4\mathcal{H} + \frac{\rho'_{\text{a}} + \mathcal{P}'_{\text{a}}}{\rho_{\text{a}} + \mathcal{P}_{\text{a}}}\right]\Theta_{\text{a}} + \frac{\nabla^2\delta p_{\text{g a}}}{\rho_{\text{a}} + \mathcal{P}_{\text{a}}} + \nabla^2\Phi \\ & - 3\frac{\mathcal{H}}{a(\rho_{\text{a}} + \mathcal{P}_{\text{a}})}\nabla^2\Xi_{\text{a}} - \frac{\bar{\xi}_{\text{a}}[\nabla^2\Theta_{\text{a}} - 3\nabla^2(\Psi' + \mathcal{H}\Phi)]}{a(\rho_{\text{a}} + \mathcal{P}_{\text{a}})} = -a\bar{\Gamma}\frac{\rho_{\text{a}} + p_{\text{a}}}{\rho_{\text{a}} + \mathcal{P}_{\text{a}}}\Theta, \end{aligned} \quad (3.38)$$

$$\begin{aligned} & \Theta'_{\text{b}} + \left[4\mathcal{H} + \frac{\rho'_{\text{b}} + \mathcal{P}'_{\text{b}}}{\rho_{\text{b}} + \mathcal{P}_{\text{b}}}\right]\Theta_{\text{b}} + \frac{\nabla^2\delta p_{\text{g b}}}{\rho_{\text{b}} + \mathcal{P}_{\text{b}}} + \nabla^2\Phi \\ & - 3\frac{\mathcal{H}}{a(\rho_{\text{b}} + \mathcal{P}_{\text{b}})}\nabla^2\Xi_{\text{b}} - \frac{\bar{\xi}_{\text{b}}[\nabla^2\Theta_{\text{b}} - 3\nabla^2(\Psi' + \mathcal{H}\Phi)]}{a(\rho_{\text{a}} + \mathcal{P}_{\text{b}})} = a\bar{\Gamma}\frac{\rho_{\text{a}} + p_{\text{a}}}{\rho_{\text{b}} + \mathcal{P}_{\text{b}}}\Theta. \end{aligned} \quad (3.39)$$

In Eqs. (3.36), (3.37) and (3.38), (3.39), $\delta\rho_{\text{a g}}$ and $\delta\rho_{\text{b g}}$ denote the gauge-invariant energy density fluctuations of the two species. A similar notation has been employed for the fluctuations in the pressure densities (i.e. $\delta p_{\text{a g}}$ and $\delta p_{\text{b g}}$) and for the gauge-invariant fluctuations of the velocity field (i.e. Θ_{a} and Θ_{b}). A useful remark is that Eqs. (3.38) and (3.39) imply a transfer of momentum between the a-fluid and the b-fluid.

The total gauge-invariant fluctuations are easily related to the gauge-invariant fluctuations of the single species, i.e.

$$\delta\rho_{\text{g}} = \delta\rho_{\text{g a}} + \delta\rho_{\text{g b}}, \quad (3.40)$$

$$\delta p_{\text{g}} = \delta p_{\text{g a}} + \delta p_{\text{g b}}, \quad (3.41)$$

$$(\rho + p)\Theta = (\rho_{\text{a}} + p_{\text{a}})\Theta_{\text{a}} + (\rho_{\text{b}} + p_{\text{b}})\Theta_{\text{b}}, \quad (3.42)$$

$$\bar{\xi}\Theta = \bar{\xi}_{\text{a}}\Theta_{\text{a}} + \bar{\xi}_{\text{b}}\Theta_{\text{b}}, \quad (3.43)$$

$$\Xi = \Xi_{\text{a}} + \Xi_{\text{b}}. \quad (3.44)$$

From Eqs. (3.42) and (3.43), it follows that the total velocity field can also be written as

$$(\rho + \mathcal{P})\Theta = (\rho_{\text{a}} + \mathcal{P}_{\text{a}})\Theta_{\text{a}} + (\rho_{\text{b}} + \mathcal{P}_{\text{b}})\Theta_{\text{b}}, \quad (3.45)$$

where, we recall, $\mathcal{P} = \mathcal{P}_a + \mathcal{P}_b$.

It is clear that summing up Eq. (3.36) and Eq. (3.37), the temporal component of the covariant conservation equation for the total fluid is recovered, i.e.

$$\begin{aligned} & \delta\rho'_g + 3\mathcal{H}(\delta\rho_g + \delta p_g) - 9\frac{\mathcal{H}}{a}\Xi + (\rho_a + \mathcal{P}_a)\Theta \\ & - 3(\rho + \mathcal{P})\Psi' - \frac{3}{a}\mathcal{H}\bar{\xi}[\Theta - 3(\Psi' + \mathcal{H}\Phi)] = 0. \end{aligned} \quad (3.46)$$

Similarly, summing up Eq. (3.38) and Eq. (3.39), the spatial component of the covariant conservation equation for the total fluid becomes

$$\begin{aligned} & \Theta' + \left[4\mathcal{H} + \frac{(\rho' + \mathcal{P}')}{\rho + \mathcal{P}}\right]\Theta + \frac{\nabla^2\delta p_g}{\rho + \mathcal{P}} + \nabla^2\Phi \\ & - 3\frac{\mathcal{H}}{a(\rho + \mathcal{P})}\nabla^2\Xi - \frac{\bar{\xi}[\nabla^2\Theta - 3\nabla^2(\Psi' + \mathcal{H}\Phi)]}{\rho + \mathcal{P}} = 0. \end{aligned} \quad (3.47)$$

As a final comment, it could be noted that while, in the case of the background, the effect of the bulk viscosity coefficient is to renormalize the effective pressure densities, at the level of the fluctuations this simplification is no longer possible as is evident, for instance, from Eq. (3.27). In a complementary perspective, the presence of spatial fluctuations in the bulk viscosity coefficient induces some sort of intrinsic non-adiabatic pressure density variation. Each of the fluids of the mixture will have an inviscid contribution and a viscous contribution. In the limits $\bar{\xi}_{a,b} \rightarrow 0$ and $\Xi_{a,b} \rightarrow 0$, the fluid becomes inviscid both at the level of the background and at that of the fluctuations. The inviscid contribution can be characterized, in the simplest case, by two barotropic indices and by the two sound speeds, i.e.

$$w_{a,b} = \frac{p_{a,b}}{\rho_{a,b}}, \quad c_{sa}^2 = \frac{\delta p_{ga}}{\delta \rho_{ga}}, \quad c_{sb}^2 = \frac{\delta p_{gb}}{\delta \rho_{gb}}, \quad (3.48)$$

where, in the first equation, the subscript means that the relation holds independently for each fluid. We are now in a condition to derive the evolution equations of the curvature and entropy perturbations in the case when both the decay rate and the bulk viscosity coefficient experience some spatial variation.

4 Curvature and entropy perturbations

The curvature fluctuations usually discussed in the theory of cosmological perturbations [29, 49, 50, 51] are indeed perturbations of the spatial curvature on comoving orthogonal hypersurfaces (see, for instance, [52]). Gauge-invariant curvature fluctuations can be defined, in terms of the Bardeen potentials, as

$$\mathcal{R} = -\left[\Psi + \frac{\mathcal{H}}{\mathcal{H}^2 - \mathcal{H}'}(\mathcal{H}\Phi + \Psi')\right] = -(\Psi - \mathcal{H}V_g), \quad (4.1)$$

where, in the second equality, we used the notation ⁶ $\Theta = \nabla^2 V_g$. Note that the second equality follows by using the momentum constraint. Suppose, indeed, to be in the comoving orthogonal gauge where, by definition $(v_C + B_C) = 0$. In this gauge, the fluctuations of the spatial curvature are related to ψ_C . Suppose now to shift by an infinitesimal quantity ϵ_0 the conformal time coordinate τ_C , i.e.

$$\tau_C \rightarrow \tau = \tau_C + \epsilon_0. \quad (4.2)$$

Under the coordinate shift (4.2), both ψ_C and $(v_C + B_C)$ transform as

$$(v_C + B_C) \rightarrow v + B = v_C + B_C + \epsilon_0, \quad (4.3)$$

$$\psi_C \rightarrow \psi = \psi_C + \mathcal{H}\epsilon_0. \quad (4.4)$$

Consequently, the expression of ψ_C in the new coordinate system defined by Eq. (4.2) is simply

$$\psi_C = \psi - \mathcal{H}(v + B) = (\Psi - \mathcal{H}V_g). \quad (4.5)$$

In the first equality of Eq. (4.5) the value of ϵ_0 is fixed by Eq. (4.3). The second equality of Eq. (4.5) follows, instead, from the definition of gauge-invariant fluctuations of Eqs. (3.20) and (3.23). Clearly, up to a sign (this is a matter of conventions) Eq. (4.5) is exactly Eq. (4.1). While in the comoving orthogonal gauge, $\mathcal{R}$ is related to fluctuations of the spatial curvature, in a different coordinate system $\mathcal{R}$ will have the same numerical value (by gauge-invariance) but will not necessarily be related to curvature fluctuations.

There is also another physical quantity that plays an important rôle in our considerations, namely the curvature fluctuation on uniform density hypersurfaces (see, for instance, [52]). The fluctuations of the (total) curvature on uniform density hypersurfaces have a gauge-invariant interpretation and they can be defined as

$$\zeta = -\left(\Psi + \mathcal{H}\frac{\delta\rho_g}{\rho'}\right). \quad (4.6)$$

As in the case discussed in Eq. (4.1), ζ coincides with a perturbation of the spatial curvature in the uniform density gauge (see, for instance, [52]). In a different coordinate system ζ will keep the same numerical value, but its physical interpretation will be different. Suppose to be in the coordinate system defined by the condition $\delta\rho_D$. This is the so-called uniform density gauge. Consider then curvature fluctuations on the uniform density hypersurfaces ψ_D . Under an infinitesimal shift of the time coordinate, ψ_D and $\delta\rho_D$ change as

$$\psi_D \rightarrow \psi = \psi_D + \mathcal{H}\epsilon_0, \quad (4.7)$$

$$\delta\rho_D \rightarrow \delta\rho = \delta\rho_D - \rho'\epsilon_0. \quad (4.8)$$

⁶In the following paragraphs of the present section the notation $\theta = \nabla^2 v$ and $\Theta = \nabla^2 V_g$ will be employed; these definitions follow naturally from the conventions of Eqs. (3.14) and (3.23).

Equations (4.7) and (4.8) imply that, in the new coordinate system,

$$\psi_D = \psi + \mathcal{H} \frac{\delta \rho}{\rho'} = \Psi + \mathcal{H} \frac{\delta \rho_g}{\rho'}, \quad (4.9)$$

where the first equality follows from Eq. (4.8) and the second from Eqs. (3.20) and (3.21). Again, up to a sign, Eq. (4.9) coincides with Eq. (4.6). This means that ζ parametrizes fluctuations in the spatial curvature computed on uniform density hypersurfaces. In a different gauge the numerical value of ζ will remain the same but its interpretation may be completely different.

By taking the difference of Eqs. (4.1) and (4.6) and by using the Hamiltonian constraint in its gauge-invariant form, i.e. Eq. (3.25), the following relation between $\mathcal{R}$ and ζ can be obtained:

$$\mathcal{R} = \zeta - \frac{\nabla^2 \Psi}{12\pi G a^2 (\rho + \mathcal{P})}, \quad (4.10)$$

where, as usual, $\mathcal{P}$ is the total shifted pressure of the mixture. Equation (4.10) implies that, up to Laplacians of Ψ , $\mathcal{R} \simeq \zeta$. Equation (4.10) generalizes the relation between $\mathcal{R}$ and ζ to the case when the bulk viscosity coefficient is non-vanishing. In fact, in the denominator at the right-hand side of Eq. (4.10) there appears $\mathcal{P}$, i.e. the sum of inviscid and viscous contributions to the background pressure.

As elaborated, Eq. (4.6) describes curvature fluctuations on uniform density hypersurfaces. In the same spirit, it is also possible to define the curvature fluctuations on the hypersurfaces where the energy densities of either the a-fluid or the b-fluid are uniform, namely:

$$\zeta_a = - \left(\Psi + \mathcal{H} \frac{\delta \rho_{g a}}{\rho'_a} \right), \quad (4.11)$$

$$\zeta_b = - \left(\Psi + \mathcal{H} \frac{\delta \rho_{g b}}{\rho'_b} \right), \quad (4.12)$$

where, according to Eqs. (3.36) and (3.37), $\delta \rho_{g a}$ and $\delta \rho_{g b}$ are the gauge-invariant density fluctuations of each fluid of the mixture. In equivalent terms, Eqs. (4.11) and (4.12) can also be interpreted as related to the density fluctuations on the hypersurfaces where the curvature is homogeneous (this point of view will be particularly useful for the considerations of the following section).

From the gauge-invariant definitions given in Eqs. (4.6) and (4.11), (4.12) it is easy to show that

$$\zeta = \frac{\rho'_a}{\rho'} \zeta_a + \frac{\rho'_b}{\rho'} \zeta_b. \quad (4.13)$$

While the weighted sum of ζ_a and ζ_b is related to ζ , the difference between them is related to the entropy fluctuations. More specifically, the relative fluctuations in the specific entropy

ς can be written as

$$\mathcal{S} = \frac{\delta\varsigma}{\varsigma} = -3(\zeta_a - \zeta_b). \quad (4.14)$$

In the limit of vanishing decay rate and vanishing bulk viscous stresses (for two perfect, inviscid, non-interacting fluids), Eq. (4.14) becomes

$$\mathcal{S} = \frac{\delta_{g a}}{(1 + w_a)} - \frac{\delta_{g b}}{(1 + w_b)}, \quad (4.15)$$

where $\delta_{g a} = \delta\rho_{g a}/\rho_a$ and $\delta_{g b} = \delta\rho_{g b}/\rho_b$ are the gauge-invariant density contrasts; w_a and w_b are the barotropic indices for the two fluids of the mixture. Equation (4.15) coincides with the definition of Ref. [19] and it applies, for instance, in the discussion of CDM-radiation isocurvature mode in the absence of decay rates. In more general situations, for instance when decay rates are included, Eq. (4.14) does not reduce to Eq. (4.15) [27]. Recalling Eqs. (4.11) and (4.12), Eq. (4.14) can also be written as

$$\mathcal{S} = 3\mathcal{H}\left(\frac{\delta\rho_{g a}}{\rho'_a} - \frac{\delta\rho_{g b}}{\rho'_b}\right). \quad (4.16)$$

Let us now define the quantities relevant to the evolution of curvature perturbations. The total pressure density appearing in Eq. (3.27) can always be split as

$$\delta p_g = \left(\frac{\delta p_g}{\delta\rho_g}\right)_\varsigma \delta\rho_g + \left(\frac{\delta p_g}{\delta\varsigma}\right)_\rho \delta\varsigma, \quad (4.17)$$

where the two subscripts imply that the two relative variations at the right-hand side should be taken, respectively, at *constant* entropy and energy densities. Thus, to perform the variation at constant (total) energy density means that $\delta\rho_{g a} = -\delta\rho_{g b}$. Similarly, to perform the variation at constant ς means that $\delta\varsigma = 0$, i.e. from Eq. (4.16)

$$\frac{\delta\rho_{g a}}{\rho'_a} = \frac{\delta\rho_{g b}}{\rho'_b}. \quad (4.18)$$

Notice also that, for practical purposes, it is often useful to denote the whole second term at the right-hand side of Eq. (4.17) as δp_{nad} .

In the case of two fluids the total speed of sound and the non-adiabatic pressure density variation are:

$$c_s^2 = \left(\frac{\delta p_g}{\delta\rho_g}\right)_\varsigma = \frac{c_{s a}^2 \rho'_a + c_{s b}^2 \rho'_b}{\rho'_a + \rho'_b}, \quad (4.19)$$

$$\delta p_{nad} = \left(\frac{\delta p}{\delta\varsigma}\right)_\rho \delta\varsigma = -\frac{(c_{s a}^2 - c_{s b}^2) \rho'_a \rho'_b}{\mathcal{H}(\rho'_a + \rho'_b)} (\zeta_a - \zeta_b), \quad (4.20)$$

where the speeds of sound in the two fluids of the mixture have been explicitly introduced. Recalling the connection between ς and the weighted sum of ζ_a and ζ_b , i.e. Eq. (4.13), it

is also possible to write δp_{nad} in an alternative useful form:

$$\delta p_{\text{nad}} = \frac{(c_{\text{s,b}}^2 - c_{\text{s,a}}^2)\rho'_a}{\mathcal{H}}(\zeta_a - \zeta), \quad (4.21)$$

where, according to Eq. (3.48) the speeds of sound refer to the inviscid contribution to the total energy-momentum tensor. Thus $c_{\text{s,b}}^2 = w_{\text{b}}$ and $c_{\text{s,a}}^2 = w_{\text{a}}$.

Taking now the difference between Eqs. (3.27) and (3.25), and recalling Eqs. (4.1) and (4.17), the evolution of $\mathcal{R}$ can be obtained easily, and it turns out to be

$$\begin{aligned} \mathcal{R}' &= \frac{3\mathcal{H}}{a(\rho + \mathcal{P})}\bar{\xi}'(\mathcal{R} + \Psi) - \frac{\mathcal{H}}{\rho + \mathcal{P}}\delta p_{\text{nad}} + \frac{3\mathcal{H}^2}{a(\rho + \mathcal{P})}\Xi \\ &+ \frac{\bar{\xi}}{a}\frac{\mathcal{H}}{\rho + \mathcal{P}}\Theta - \frac{\mathcal{H}c_{\text{s}}^2}{4\pi Ga^2(\rho + \mathcal{P})}\nabla^2\Psi. \end{aligned} \quad (4.22)$$

We can also write the above expression directly in terms of ζ , i.e. as the density contrast on uniform density hypersurfaces. Recalling Eq. (4.10) we can also write

$$\begin{aligned} \mathcal{R}' &= \zeta' - \frac{\nabla^2\Psi'}{12\pi Ga^2(\rho + \mathcal{P})} - \frac{\mathcal{H}(3c_{\text{s}}^2 + 1)}{12\pi Ga^2(\rho + \mathcal{P})}\nabla^2\Psi \\ &- \frac{\mathcal{H}}{4\pi Ga^2(\rho + \mathcal{P})^2}\frac{\bar{\xi}'}{a}\nabla^2\Psi + \frac{\bar{\xi}}{a(\rho + \mathcal{P})}\nabla^2\Psi. \end{aligned} \quad (4.23)$$

by simply taking the conformal-time derivatives of the left- and of the right-hand sides. Inserting Eq. (4.23) into Eq. (4.22) and using the gauge-invariant form of the momentum constraint given in Eq. (3.26), we simply obtain

$$\begin{aligned} \zeta' &= \frac{3\mathcal{H}}{a(\rho + \mathcal{P})}\bar{\xi}'\zeta - \frac{\mathcal{H}}{\rho + \mathcal{P}}\delta p_{\text{nad}} + \frac{3\mathcal{H}}{a(\rho + \mathcal{P})}(\mathcal{H}\Xi + \bar{\xi}'\Psi) \\ &+ \Theta\left[\frac{\bar{\xi}\mathcal{H}}{a(\rho + \mathcal{P})} - \frac{1}{3}\right] - \frac{\mathcal{H}}{12\pi Ga^2(\rho + \mathcal{P})}\nabla^2(\Phi - \Psi) - \frac{\bar{\xi}}{a(\rho + \mathcal{P})}\nabla^2\Psi. \end{aligned} \quad (4.24)$$

Concerning Eq. (4.24), a few comments are in order:

- the first three terms on the right-hand side of Eq. (4.24) dominate over length scales larger than the Hubble radius; the remaining terms in the second line of Eq. (4.24) are subleading in this limit;
- when $\bar{\xi} \rightarrow 0$ and $\Xi \rightarrow 0$ (i.e. in the case of vanishing homogeneous and inhomogeneous viscosity), Eq. (4.24) reduces to the usual form of the evolution equation for ζ (note, in fact, that in this limit $\mathcal{P} \rightarrow p$);
- since δp_{nad} contains both ζ and ζ_a (being proportional to the fluctuations of the entropy density), the evolution of ζ is completely specified only when coupled to the evolution of ζ_a .

Therefore, to have a self-consistent system of differential equations for length scales larger than the Hubble radius, it is mandatory to derive an evolution equation for ζ_a . This can be deduced by inserting $\delta\rho_{g_a}$ (obtained from Eq. (4.11)) into Eq. (3.36). The result of this algebraic operation can then be written as

$$\begin{aligned}
& (\zeta_a + \Psi)' + (\zeta_a + \Psi) \left[\frac{\mathcal{H}}{\rho'_a} \left(\frac{\rho'_a}{\mathcal{H}} \right)' + 3\mathcal{H}(c_{s_a} + 1) + a\bar{\Gamma}(c_{s_a} + 1) \right] \\
& + \frac{9\mathcal{H}^3}{a\rho'_a} \bar{\Xi}_a - \frac{\mathcal{H}(\rho_a + \mathcal{P}_a)}{\rho'_a} \Theta_a \\
& \frac{3\mathcal{H}(\rho_a + \mathcal{P}_a)}{\rho'_a} \Psi' + \frac{3}{a} \frac{\mathcal{H}^2}{\rho'_a} \bar{\xi}_a \left[\Theta_a - 3 \frac{(\mathcal{H}' - \mathcal{H}^2)}{\mathcal{H}} (\mathcal{R} + \Psi) \right] \\
& = a(p_a + \rho_a) \bar{\Gamma} \frac{\mathcal{H}}{\rho'_a} \left[\delta_{\Gamma_g} + \frac{\mathcal{H}' - \mathcal{H}^2}{\mathcal{H}^2} \mathcal{R} \right] - a \frac{(p_a + \rho_a)}{\rho'_a} \bar{\Gamma} \left[\Psi' + \frac{\mathcal{H}^2 - \mathcal{H}'}{\mathcal{H}} \Psi \right]. \quad (4.25)
\end{aligned}$$

where

$$\delta_{\Gamma_g} = \frac{\delta\Gamma_g}{\bar{\Gamma}}. \quad (4.26)$$

is the fractional fluctuation of the decay rate.

Equation (4.25) can be simplified by using the evolution equations of the background and, in particular, the background conservation equation for the a-fluid, i.e. Eq. (3.8). This observation allows us to eliminate the various terms proportional to Ψ' and to Ψ . The second achievable simplification is to trade $\mathcal{R}$ for ζ . This operation, according to Eq. (4.10), will bring some extra terms proportional to $\nabla^2 \Psi$. In the case where the inviscid part of the a-fluid has a barotropic index w_a , the speed of sound is given by $c_{s_a}^2 = w_a$. In this case the quantity

$$g_a = -\frac{\mathcal{H}(1 + w_a)\rho_a}{\rho'_a}, \quad (4.27)$$

can be defined.

Taking into account all these simplifications, Eq. (4.25) can be written as

$$\begin{aligned}
& \zeta'_a + \left[\frac{9\mathcal{H}^2}{a} \frac{\bar{\xi}_a}{\rho_a} - \frac{g'_a}{g_a} \right] \zeta_a + \frac{9\mathcal{H}^2}{a\rho'_a} [\mathcal{H}\bar{\Xi}_a + \bar{\xi}'_a \Psi] \\
& + \frac{3\mathcal{H}^2}{a\rho'_a} \bar{\xi}_a \left[\Theta_a + 3 \frac{\mathcal{H}^2 - \mathcal{H}'}{\mathcal{H}} \zeta \right] + 3 \frac{\mathcal{H}\bar{\xi}_a}{a\rho'_a} \nabla^2 \Psi \\
& = -a\bar{\Gamma}g_a \left[\left(\delta_{\Gamma} + \frac{\bar{\Gamma}'}{\bar{\Gamma}\mathcal{H}} \Psi \right) + \frac{\mathcal{H}' - \mathcal{H}^2}{\mathcal{H}^2} \zeta \right] - a\bar{\Gamma} \frac{g_a}{3\mathcal{H}^2} \nabla^2 \Psi \quad (4.28)
\end{aligned}$$

In Eq. (4.28), several terms are subleading for length scales larger than the Hubble radius. Thus, we can rewrite Eqs. (4.24) and (4.28) in the cosmic time coordinate, keeping only the dominant terms for length scales larger than the Hubble radius. The result is given by

$$\dot{\zeta} = \frac{3H}{(\rho + \mathcal{P})} \dot{\bar{\xi}} \zeta - \frac{H}{\rho + \mathcal{P}} \delta p_{\text{nad}} + \frac{3H}{(\rho + \mathcal{P})} (H\bar{\Xi} + \dot{\bar{\xi}} \Psi) \quad (4.29)$$

and by

$$\begin{aligned}
& \dot{\zeta}_a + \left[9H^2 \frac{\bar{\xi}_a}{\rho_a} - \frac{\dot{g}_a}{g_a} \right] \zeta_a + \frac{9H^2}{a\dot{\rho}_a} [H\Xi_a + \dot{\bar{\xi}}_a \Psi] - \frac{9H\dot{H}}{\dot{\rho}_a} \bar{\xi}_a \zeta \\
& = -\bar{\Gamma} g_a \left[\left(\delta_\Gamma + \frac{\dot{\bar{\Gamma}}}{\bar{\Gamma}H} \Psi \right) + \frac{\dot{H}}{H^2} \zeta \right].
\end{aligned} \tag{4.30}$$

Equations (4.29) and (4.30) can be used, for instance, to study numerically the evolution of fluctuations whose wavelength is larger than the Hubble radius, with two caveats. The first caveat is that g_a has to be always non-singular. This may not always be the case when a viscous contribution is present. In this case, instead of studying the evolution of ζ_a it will be more practical to deal directly with δ_{g_a} , i.e. the gauge-invariant density contrast. The second remark is that, apparently, Eqs. (4.29) and (4.30) require the independent determination of Ψ . The evolution equation for Ψ can be directly obtained in terms of ζ from Eqs. (4.1) and (4.10). As will be shown in the next section, the coupled evolution of ζ_a and ζ can also be easily integrated directly in a specific gauge, i.e. the so-called off-diagonal gauge [53] (see also [54] and [52]).

It is appropriate to remark here that in the case of homogeneous decay rate (i.e. $\delta_{\Gamma_g} = 0$) and in the absence of homogeneous and inhomogeneous viscosity (i.e. $\bar{\xi}_a = \bar{\xi}_b = 0$ and $\Xi_a = \Xi_b = 0$), Eqs. (4.29) and (4.30) become simply, in units $8\pi G = 1$,

$$\dot{\zeta} = \frac{w_b - w_a}{\rho + p} \dot{\rho}_a (\zeta - \zeta_a), \tag{4.31}$$

$$\dot{\zeta}_a = \bar{\Gamma} g_a \frac{\dot{H}}{H^2} (\zeta_a - \zeta). \tag{4.32}$$

Equation (4.31) can be deduced from Eq. (4.29) using Eq. (4.20) in the specific case $c_{s,a}^2 = w_a$ and $c_{s,b}^2 = w_b$. To get to Eq. (4.31) it is also useful to recall that ζ_b can be always eliminated through Eq. (4.13). Note that in Eq. (4.31), at the right-hand side, the denominator reads $(\rho + p)$ and not $(\rho + \mathcal{P})$ since $\mathcal{P} \rightarrow p$ in the limit $\bar{\xi} = 0$. Equation (4.32) can be obtained from Eq. (4.30) by making explicit the expressions depending on g_a and by using Eq. (2.15) always in the case $c_{s,a}^2 = w_a$.

5 Off-diagonal gauge description

In the off-diagonal gauge, the diagonal entries of the perturbed metric are set to zero, i.e. $\delta_s g_{ij} = 0$ in Eq. (3.5). More precisely, in the off-diagonal gauge,

$$\psi_{\text{od}} = 0, \quad E_{\text{od}} = 0. \tag{5.1}$$

From a generic perturbed line element where all the entries of the perturbed metric do not vanish, the off-diagonal coordinate system can be reached by performing a coordinate transformation

$$\begin{aligned}\tau &\rightarrow \tilde{\tau} = \tau + \epsilon_0, \\ x_i &\rightarrow \tilde{x}_i = x_i + \partial_i \lambda.\end{aligned}\tag{5.2}$$

The shift (5.2) induces a transformation in the $\delta_s g_{ij}$ components of the perturbed metric:

$$\begin{aligned}\psi &\rightarrow \psi_{\text{od}} = \psi + \mathcal{H}\epsilon_0, \\ E &\rightarrow E_{\text{od}} = E - \lambda.\end{aligned}\tag{5.3}$$

The gauge parameters are completely fixed to $\lambda = E$ and $\epsilon_0 = -\psi/\mathcal{H}$ since, as introduced above, $\psi_{\text{od}} = E_{\text{od}} = 0$. In the off-diagonal gauge the curvature is then uniform, i.e. $\psi_{\text{od}} = 0$. This is the reason why the off-diagonal gauge is also correctly named uniform-curvature gauge.

In the off-diagonal coordinate system, the gauge-invariant variables ζ_a and ζ_b defined in the previous section are simply proportional to the relative density contrasts of the two fluids, i.e.

$$\begin{aligned}\zeta_a &= -\mathcal{H} \frac{\delta \rho_a}{\rho'_a} = -\mathcal{H} \frac{\rho_a}{\rho'_a} \delta_a \\ \zeta_b &= -\mathcal{H} \frac{\delta \rho_b}{\rho'_b} = -\mathcal{H} \frac{\rho_b}{\rho'_b} \delta_b,\end{aligned}\tag{5.4}$$

where δ_a and δ_b are the density contrasts computed in the off-diagonal gauge.

The evolution equations in the off-diagonal gauge can be obtained directly from the Eqs. (3.15), (3.16) and (3.17)-(3.18) by setting E and ψ to 0. With this strategy in mind the Hamiltonian and momentum constraints read, respectively ⁷,

$$-\mathcal{H}\nabla^2 B - 3\mathcal{H}^2\phi = 4\pi G a^2 \delta\rho,\tag{5.5}$$

$$\mathcal{H}\nabla^2\phi + (\mathcal{H}^2 - \mathcal{H}')\nabla^2 B = -4\pi G a^2 (p + \rho)\theta,\tag{5.6}$$

while the $(i = j)$ and $(i \neq j)$ components of the perturbed equations of motion are, respectively,

$$(\mathcal{H}^2 + 2\mathcal{H}')\phi + \mathcal{H}\phi' = 4\pi G a^2 \delta p,\tag{5.7}$$

$$B' + 2\mathcal{H}B + \phi = 0.\tag{5.8}$$

⁷In the following, without ambiguity, ϕ , B , θ and all the other perturbation variables are meant to be evaluated in the off-diagonal gauge.

The covariant conservation of the perturbed energy-momentum tensor implies, instead,

$$\delta\rho'_a + 3\mathcal{H}(\delta\rho_a + \delta p_a) + (\rho_a + p_a)\theta_a = -a(\rho_a + p_a)\bar{\Gamma}\left(\delta_\Gamma + \phi + \frac{\delta\rho_a + \delta p_a}{\rho_a + p_a}\right), \quad (5.9)$$

$$\delta\rho'_b + 3\mathcal{H}(\delta\rho_b + \delta p_b) + (\rho_b + p_b)\theta_b = a(p_a + \rho_a)\bar{\Gamma}\left(\delta_\Gamma + \phi + \frac{\delta\rho_a + \delta p_a}{\rho_a + p_a}\right). \quad (5.10)$$

In the off-diagonal gauge the explicit form of the evolution equations for ζ and ζ_a (amputated to the leading terms that are relevant for length scales larger than the Hubble radius) are:

$$\dot{\zeta} = -\frac{3H}{2\dot{H}}[H(\delta\xi_a + \delta\xi_b) + (\dot{\bar{\xi}}_a + \dot{\bar{\xi}}_b)\zeta] + \frac{1}{2\dot{H}}(w_b - w_a)\dot{\rho}_a(\zeta_a - \zeta), \quad (5.11)$$

where we traded $(\rho + \mathcal{P})$ for $-2\dot{H}$, as follows from Eq. (2.9) (when units $8\pi G = 1$ are used⁸). The evolution equation for ζ_a is then

$$\dot{\zeta}_a + \left(9H^2\frac{\bar{\xi}_a}{\rho_a} - \frac{\dot{g}_a}{g_a}\right)\zeta_a + \frac{9H}{\dot{\rho}_a}(H^2\delta\xi_a - \dot{H}\bar{\xi}_a\zeta) = -\bar{\Gamma}g_a\left(\delta_\Gamma + \frac{\dot{H}}{H^2}\zeta\right). \quad (5.12)$$

To derive Eqs. (5.11) and (5.12) directly in the off-diagonal gauge, it is useful to notice that, in this coordinate system, the relation of ζ to ϕ is particularly simple and it is given by

$$\zeta = -\frac{\mathcal{H}^2}{\mathcal{H}^2 - \mathcal{H}'}\phi \equiv \frac{H^2}{\dot{H}}\phi. \quad (5.13)$$

As previously discussed, it is useful for some applications to study curvature fluctuations directly in the ζ, δ_a parametrization where the evolution equations read:

$$\dot{\zeta} = -\frac{3H}{2\dot{H}}[H(\delta\xi_a + \delta\xi_b) + (\dot{\bar{\xi}}_a + \dot{\bar{\xi}}_b)\zeta] - \frac{1}{2\dot{H}}(w_b - w_a)(H\rho_a\delta_a + \dot{\rho}_a\zeta), \quad (5.14)$$

$$\dot{\delta}_a + \frac{9H^2}{\rho_a}\left(\bar{\xi}_a\delta_a - \delta\xi_a + \bar{\xi}_a\frac{\dot{H}}{H^2}\zeta\right) = -\bar{\Gamma}(1 + w_a)\left(\delta_\Gamma + \frac{\dot{H}}{H^2}\zeta\right). \quad (5.15)$$

Notice that Eqs. (5.11) and (5.12) can be swiftly deduced from Eqs. (4.29) and (4.30), by expressing the gauge-invariant fluctuations directly in the off-diagonal gauge. The only non-trivial expressions are

$$\mathcal{H}\Xi + \bar{\xi}'\Psi = \mathcal{H}\delta\xi, \quad (5.16)$$

and

$$\mathcal{H}\Xi_a + \bar{\xi}'_a\Psi = \mathcal{H}\delta\xi_a. \quad (5.17)$$

The meaning of Eqs. (5.16) and (5.17) is that the two (gauge-invariant) quantities at the left-hand sides translate, in the off-diagonal gauge, simply into the spatial variations of the bulk viscosity coefficient. The right-hand sides of these equations are deduced from the

⁸In the following, without loss of generality, we will set $8\pi G = 1$.

left-hand sides by simply using Eqs. (3.20)–(3.24) (or Eqs. (3.20)–(3.34)) and by setting, in the obtained expression, $E = 0$ and $\psi = 0$.

For some applications, it is interesting to consider situations where $\dot{H} \rightarrow 0$, at least for an interval of cosmic time. This may happen if the background solutions have, in some limit, a quasi-de Sitter evolution where $\dot{H}^{-1}$ may become very large. In this case the evolution equations in terms of ζ is partially invalidated. The evolution equations in terms of ϕ are, instead, fully valid and well defined in all their limits.

From Eqs. (5.7), (5.8) and (5.9), neglecting the spatial gradients and using the cosmic time coordinate the relevant equations become

$$\begin{aligned}\dot{\phi} + \left(3H + 2\frac{\dot{H}}{H}\right)\phi &= \frac{1}{2H}\{\delta p + 3H[(\bar{\xi}_a + \bar{\xi}_b)\phi - (\delta\xi_a + \delta\xi_b)]\}, \\ \dot{\delta}_a + \frac{9H^2}{\rho_a}[\bar{\xi}_a\delta_a - \delta\xi_a + \bar{\xi}_a\phi] &= -\bar{\Gamma}(w_a + 1)[\delta_\Gamma + \phi], \\ \dot{\beta} + H\beta + \phi &= 0,\end{aligned}\tag{5.18}$$

where $aB = \beta$.

6 Physical applications

6.1 The case of vanishing background viscosity

Two complementary situations may arise. In the first case the homogeneous component of the bulk viscosity coefficient vanishes (i.e. $\bar{\xi}_a = \bar{\xi}_b = 0$) but the inhomogeneous part does not vanish (i.e. either $\delta\xi_a \neq 0$ or $\delta\xi_b \neq 0$). In this case it is plausible, from either Eqs. (4.29), (4.30) or (5.16), (5.17), that the evolution of curvature perturbations will be supplemented by a source term proportional to the spatial variations of the bulk viscosity coefficient.

This situation is, to some extent, a bit arbitrary, but it closely analogous to the situation encountered in the case of a decay rate with spatial fluctuations, i.e. the toy model when the decay rate is allowed to be inhomogeneous but without a specific microscopic model supporting this interpretation [41]. In spite of this important caveat let us investigate first this (rather extreme) situation.

Suppose, for simplicity, that $\bar{\xi}_a = \bar{\xi}_b = 0$ but $\delta\xi_b \neq 0$. In this case, it can be shown that, in spite of the value of δ_Γ , ζ increases linearly in time. In Fig. 1 the integration of Eqs. (5.11) and (5.12) is illustrated. In the plot at the left-hand side, the evolution of the energy densities of the background is reported for the case where the decay products are

Figure 1: The evolution of the background (left-hand-side plot) and of the fluctuations (right-hand-side plot) are illustrated in various cases of physical interest. The parameters are fixed in so that $\Gamma/H_0 = 10^{-3}$, $\delta_\Gamma = 10^{-7}$, $\delta\xi_b = 10^{-10}$, $\delta\xi_a = 0$. In this figure (and in the following) H_0 denotes the value of the Hubble parameter at the initial integration time.

given by a radiation fluid (i.e. $w_b = 1/3$) and the a-fluid is given by pressureless matter ($w_a = 0$). Similar plots can be obtained when $w_a \neq 0$ (for instance $w_a = 1$ or $w_a = 1/10$). In the present context it will often be interesting to fix w_b to $1/3$ and to leave w_a free to vary from 0 to 1. As is clear from Fig. 1, for $t > \bar{\Gamma}^{-1}$, the energy density of the a-fluid is exponentially damped thanks to the finite value of the decay. For curvature scales much smaller than the decay rate the radiation background dominates. In Fig. 1 (plot at the right-hand side) the evolution of ζ is compared with the analytical approximation valid for large times.

To get an analytical approximation for the evolution of ζ let us start from Eqs. (5.11) and (5.12). We are interested in the case where $\bar{\xi}_a = \bar{\xi}_b = 0$. Moreover, as assumed above, we may also posit, for simplicity, $w_a = 0$ (which is the case numerically treated in Fig. 1). Under these assumptions, Eqs. (5.11) and (5.12) become, respectively

$$\dot{\zeta} = \frac{w_b}{2\dot{H}}\dot{\rho}_a(\zeta_a - \zeta) - \frac{3H^2}{2\dot{H}}\delta\xi, \quad (6.1)$$

$$\dot{\zeta}_a = \bar{\Gamma}\frac{\dot{H}}{H^2}g_a(\zeta_a - \zeta) - \bar{\Gamma}g_a\delta_\Gamma. \quad (6.2)$$

To proceed further, notice that, from Eq. (4.27) we have, in the case $w_a = 0$

$$g_a = -\frac{H\rho_a}{\dot{\rho}_a} = \frac{H}{3H + \bar{\Gamma}} \quad (6.3)$$

where the second equality follows from the first by explicit use of the (background) continuity equation for the a-fluid in the case $w_a = 0$:

$$\dot{\rho}_a + (3H + \bar{\Gamma})\rho_a = 0. \quad (6.4)$$

Since $\bar{\Gamma}$ is constant, from Eq. (6.3) it is clear that, for large times,

$$g_a \simeq H/\bar{\Gamma}. \quad (6.5)$$

This asymptotic expression compares very well with the numerical result. In Fig. 1 (plot at the left), the first thick line from the top corresponds to the numerical evolution of $\log g_a$ while the (first) thin line (from the top) is the result obtained by approximating $g_a \sim H/\bar{\Gamma}$.

Notice, furthermore, that for sufficiently large times (i.e. $t > \bar{\Gamma}^{-1}$) the evolution of H is simply given by

$$H \simeq \frac{2}{3(w_b + 1)t}. \quad (6.6)$$

This is because the contribution of the a-fluid to the Hubble rate vanishes exponentially for $t > \bar{\Gamma}^{-1}$. In fact, from Eq. (6.4) direct integration leads to

$$\rho_a(t) = \rho_a(t_0) \left(\frac{a_0}{a} \right)^3 e^{-\bar{\Gamma}(t-t_0)}. \quad (6.7)$$

Equations (6.4)–(6.5) and (6.6)–(6.7) allow to estimate analytically the time-dependent coefficients appearing in eqs. (6.1) and (6.2). In particular, by looking at Eq. (6.1), the coefficient of the first term at the right hand side is exponentially suppressed, for $t > \bar{\Gamma}^{-1}$ since it contains $\dot{\rho}_a$ (see Eq. (6.7)). On the contrary, the coefficient of the second term at the right hand side of Eq. (6.1) is finite and it is given by (see Eq. (6.6))

$$-\frac{3}{2} \frac{H^2}{\dot{H}} = \frac{1}{w_b + 1}. \quad (6.8)$$

Since $\delta\xi$ is constant in time, direct integration of Eq. (6.1) leads to

$$\zeta \simeq \frac{\delta\xi}{w_b + 1} \left(\frac{t}{t_1} \right). \quad (6.9)$$

where $t_1 \geq \bar{\Gamma}^{-1}$. By keeping the dominant terms in the limit $t \gg \bar{\Gamma}^{-1}$ Eq. (6.2) allows also to determine the evolution of ζ_a that turns out to be of the same order of ζ . Equation (6.9) is illustrated in the right-hand plot of Fig. 1 and it compares very well with the numerical solution.

6.2 The case of non vanishing background viscosity

The following example we ought to discuss is the one where $\xi_a = \epsilon\sqrt{\rho_a}$ and $\xi_b = 0$. In this case,

$$\delta\xi_a = \epsilon \frac{\delta\rho_a}{2\sqrt{\rho_a}}, \quad \dot{\xi}_a = \epsilon \frac{\dot{\rho}_a}{2\sqrt{\rho_a}}. \quad (6.10)$$

Moreover, in the off-diagonal gauge, the following chain of equality holds

$$\delta\xi_a = \epsilon \frac{\sqrt{\rho_a}}{2} \delta_a = -\epsilon \frac{\dot{\rho}_a}{2H\sqrt{\rho_a}} \zeta_a. \quad (6.11)$$

It will be relevant, to physical applications, to analyse the case when the a-fluid decays into radiation (i.e. $w_b = 1/3$) with different values of the homogeneous decay rate and different initial values of w_a . When the a-fluid decays, for $\Gamma \sim H$, energy is transferred to the b-fluid. Different values of ϵ affect the overall normalization of the energy density of the a-fluid. However, since the a-fluid decays exponentially and the b-fluid decays as $a^{-3(w_b+1)}$ (where a is the scale factor) the a-fluid will quickly be subdominant. Different values of the initial decay rate (i.e. $\bar{\Gamma}/H_0 < 1$) may shift the onset of the b-dominated phase. It is relevant to stress, at this point, that initial conditions for the evolution of the background are set in such a way that $\rho_b(t_0) = 0$ (where t_0 is the initial integration time). Initially, around t_0 , the a-fluid dominates and it can easily be shown, recalling that $\bar{\xi}_a = \epsilon\sqrt{\rho_a}$ that the approximate solution for the evolution of the background, in this regime, is given by

$$H(t) \simeq \frac{2}{[3(w_a + 1) - 3\sqrt{3}\epsilon]t}, \quad \rho_a(t) \sim 3H^2(t), \quad t_0 \leq t < \bar{\Gamma}^{-1}. \quad (6.12)$$

In fact, for $t < \bar{\Gamma}^{-1}$ the a-fluid dominates the energy-momentum tensor, therefore from Eqs. (2.8)–(2.9) and (2.15)–(2.16) (written in units $8\pi G = 1$ that are the units employed in our numerical codes) we can obtain the following equation

$$\dot{H} = -\frac{3}{2}[(w_a + 1) - \sqrt{3}\epsilon]H^2 \quad (6.13)$$

whose integral with respect to cosmic time is exactly Eq. (6.12). For $t_0 \lesssim t < \bar{\Gamma}^{-1}$, the scale factor $a(t)$ expands (i.e. $\dot{a} > 0$) in a decelerated way (i.e. $\ddot{a} < 0$) and $\dot{H}$ never goes to zero iff $\epsilon < (w_a + 1)/\sqrt{3}$. Notice that, in the limit $\epsilon \rightarrow 0$ Eq. (6.12) is simply the expansion rate of a Universe filled with a perfect fluid ρ_a . We stress that this solution is only valid in the neighborhood of the initial integration time t_0 : later on the full numerical solution is mandatory. The mentioned features of the background solutions are illustrated in Fig. 2, where the evolution of the common logarithms of the energy density are reported as a function of the common logarithm of the cosmic time coordinate⁹. As a side remark, we may note that in Fig. 2 (plot on the left-hand side) the first two lines at the top illustrate the behaviour of the function $g_a(t)$ (defined in Eq. (4.27)) and of its approximation (valid for large times) i.e. $H/\bar{\Gamma}$. The function g_a is always regular and never vanishes. This aspect is related to the occurrence that the contribution of the bulk viscosity becomes negligible, in practice, when the b-fluid dominates.

⁹In the remaining part of the article the logarithms will always be common logarithms, i.e. logarithms to base 10.

Figure 2: Evolution of the energy densities of the a- and b-fluid for different choices of the parameters in the case when the homogeneous bulk viscosity coefficient is parametrized as $\bar{\xi}_a = \epsilon\sqrt{\rho_a}$. The thin lines always indicate the common logarithm of the energy density of the a-fluid, while the thick lines refer to the common logarithm of the energy density of the b-fluid (that dominates for $t \gg \bar{\Gamma}^{-1}$).

It is now appropriate to analyse the evolution of ζ and ζ_a . Consider, to begin with, the case where $\epsilon = 0$. Following the discussion of [41] (see also [45]), the asymptotic value of ζ is $\zeta_{\text{final}} \simeq -\delta_\Gamma/6$. This is exactly what is found numerically (see Fig. 3: lower curves in both plots at the left- and right-hand sides). In Fig. 3 the predicted asymptotic value is reported with a dashed line. As already remarked in [41] the accuracy of the estimate is controlled by the ratio $\bar{\Gamma}/H_0$. This aspect is also illustrated in Fig. 3. In the plot on the left-hand side $\bar{\Gamma}/H_0 = 10^{-3}$, while on the right-hand side $\bar{\Gamma}/H_0 = 0.1$. Even if the asymptotic value of $|\zeta/\delta_\Gamma|$ is always well approximated by $1/6$, the prediction is, comparatively, less accurate when $\bar{\Gamma}/H_0$ is larger.

When $\epsilon \neq 0$ and the discussion of [41] can be generalized. The authors of Ref. [41] notice that if $\bar{\Psi}$ is the solution of the system for $\delta_\Gamma = 0$, then the “forced” solution (corresponding to the case $\delta_\Gamma \neq 0$) can be obtained as $\Psi = \bar{\Psi} - \delta_\Gamma$. Assuming that, indeed, for large times both the curvature fluctuations ζ and the Bardeen potential Ψ go to a constant (as it is the case from the numerical analysis), we have that the final asymptotic value of Ψ in the case where $\delta_\Gamma \neq 0$ and $\epsilon \neq 0$ is given by

$$\Psi_{\text{final}} = \frac{[(3w_a + 5) - 3\sqrt{3}\epsilon](w_b + 1) - (3w_b + 5)[(w_a + 1) - \sqrt{3}\epsilon]}{(3w_b + 5)[(w_a + 1) - \sqrt{3}\epsilon]} \delta_\Gamma. \quad (6.14)$$

Recall now that, when the a-fluid has already decayed, the relation between ζ and Ψ (up to spatial gradients, i.e. for length-scales larger than the Hubble radius) is nothing but

$$\zeta_{\text{final}} = -\frac{3w_b + 5}{3(w_b + 1)} \Psi_{\text{final}}. \quad (6.15)$$

Figure 3: Evolution of curvature fluctuations in the case $\epsilon = 0$ and for different values of the homogeneous component of the decay rate.

From Eqs. (6.14) and (6.15), the final value of curvature fluctuations is then given by the following general equation:

$$\zeta_{\text{final}} = - \left\{ \frac{(w_b + 1)(3w_a + 5 - 3\sqrt{3}\epsilon) - (3w_b + 5)[(w_a + 1) - \sqrt{3}\epsilon]}{3(w_b + 1)[(w_a + 1) - \sqrt{3}\epsilon]} \right\} \delta_\Gamma, \quad (6.16)$$

where by ζ_{final} we mean, as before, the final asymptotic value in the phase dominated by the decay products, i.e. the b-fluid.

In the case $w_a = 0$ (leaving w_b undetermined) Eq. (6.16) leads to

$$\zeta_{0 \rightarrow w_b} = - \frac{[(w_b + 1)(5 - 3\sqrt{3}\epsilon) - (3w_b + 5)(1 - \sqrt{3}\epsilon)]}{3(w_b + 1)(1 - \sqrt{3}\epsilon)} \delta_\Gamma. \quad (6.17)$$

In Eq. (6.17) the subscript of ζ means that the quantity computed at the right-hand side is the asymptotic value of ζ in the case of the decay of $w_a = 0$ to $w_b \neq w_a$. The same notation will be used in the following equations.

In the case $w_b = 1/3$ (leaving w_a undetermined) Eq. (6.16) leads to

$$\zeta_{w_a \rightarrow 1/3} = - \frac{1}{6} \left[\frac{(1 - 3w_a) + 3\sqrt{3}\epsilon}{w_a + 1 - \sqrt{3}\epsilon} \right] \delta_\Gamma. \quad (6.18)$$

By setting $w_b = 1/3$ in Eq. (6.17) we will get the result valid for the case of a mixture of dust matter and radiation, i.e.

$$\zeta_{0 \rightarrow 1/3} = - \frac{1}{6} \left(\frac{1 + 3\sqrt{3}\epsilon}{1 - \sqrt{3}\epsilon} \right) \delta_\Gamma. \quad (6.19)$$

If we set $w_a = 1$ in Eq. (6.18), we deduce that

$$\zeta_{1 \rightarrow 1/3} = \frac{1}{6} \frac{2 - 3\sqrt{3}\epsilon}{2 - \sqrt{3}\epsilon} \delta_\Gamma. \quad (6.20)$$

Figure 4: The analytical results obtained from Eq. (6.16) are compared with the numerical calculation for the evolution of ζ for the transition dust-radiation (left plot) and for the transition stiff-radiation.

By setting $\epsilon \rightarrow 0$ in Eq. (6.19) the usual result (valid in the absence of bulk viscosity) is reproduced. It is an amusing numerical coincidence that, in the limit $\epsilon \rightarrow 0$, $\zeta_{0 \rightarrow 1/3} = -\zeta_{1 \rightarrow 1/3}$, i.e. $|\zeta_{0 \rightarrow 1/3}| = |\zeta_{1 \rightarrow 1/3}| = 1/6$.

These results compare rather well with the numerical integration of the full system. In Fig. 4 we report the result for the numerical integration of the fluctuations in terms of the logarithm of $|\zeta/\delta_\Gamma|$. The plot at the left has to be compared with the prediction of Eq. (6.19) (appropriate for a transition dust-radiation transition), while the plot at the right has to be compared with Eq. (6.20) (appropriate for a stiff-radiation transition). In both plots the predictions of, respectively, Eqs. (6.19) and (6.20) is illustrated with a dashed line. For comparison, we also report the expectation obtainable in the limit $\epsilon \rightarrow 0$. The numerical correctness of Eq. (6.16) seems then numerically justified. In Fig. 5 the integration of the evolution equations of the fluctuations is reported for different values of ϵ and δ_Γ .

In more general terms one can think of cases when $\xi_a = \epsilon \rho_a^m$. In the absence of a decay rate (and for a single fluid) [7], if $m > 1/2$, there exist general deflationary solutions beginning in a quasi-de Sitter stage that evolve away from it for large times. Always in the absence of decay rate (and always in the single fluid case) [7], if $m < 1/2$ the solution starts expanding and reaches, for large times, a quasi-de Sitter solution. These statements hold, as stressed, for the case of a single fluid and in the absence of a decay rate. If there are many fluids, allowed to decay, the evolution depends upon the relative balance of the different parameters of the model. The main end of the present approach is to investigate the situations when the bulk viscosity coefficient does not dominate for large positive times. In this sense, solutions that do not lead to a radiation-dominated background for $t > 1/\bar{\Gamma}$ are less interesting for the present analysis (but may be relevant in related contexts).

Figure 5: The integration of the evolution equations of the fluctuations is reported for different mixtures of fluids. In the plot at the left $\delta_\Gamma = 10^{-6}$, at the right $\delta_\Gamma = 10^{-8}$.

In this perspective, even if $m < 1/2$, it could happen that radiation dominates very quickly if the decay rate is sufficiently large and ϵ is sufficiently small. Consider, for instance, the case illustrated in Fig. 6, where we took $\xi_a = \epsilon \rho_a^{1/4}$. If $\bar{\Gamma}/H_0 = 0.1$ and $\epsilon = 10^{-3}$ the evolution equations can be integrated. To be safe, the evolution equations of the fluctuations may be integrated directly in the off-diagonal gauge in terms of ϕ (not of ζ). This choice has the advantage that the evolution of ϕ is never singular even if $\dot{H} \rightarrow 0$ during a possible quasi-de Sitter stage. Also other cases of this rich system may be physically relevant. Those presented here were selected because they illustrate, in simple terms, the interplay between bulk viscous stresses and fluctuating decay rates.

7 Concluding remarks

Bulk viscous effects of interacting relativistic fluids have been investigated. These two effects were never considered simultaneously, to the best of our knowledge. The energy-momentum tensors of each of the fluids of the relativistic plasma have been parametrized as the sum of an inviscid contribution and of a bulk viscous correction. Different results have been obtained:

- a fully gauge-invariant description of the evolution of the fluctuations of the geometry has been discussed in the presence of both a fluctuating decay rate and a fluctuating bulk viscosity coefficient;
- gauge-dependent descriptions have been derived and exploited with particular attention to the off-diagonal (or uniform-curvature) gauge.

Figure 6: The integration of the system is illustrated in the case $\xi_a = \epsilon \rho_a^{1/4}$ and $\xi_b = 0$. The value $\delta_\Gamma = 10^{-8}$ has been used. In the plot on the left-hand side the evolution of the background energy density is reported on a double logarithmic scale. On the right-hand-side plot the evolution of ζ and ζ_a is reported for the same background values used in the left hand one.

- if the bulk viscosity coefficient and the decay rate are allowed to have spatial variation on super-horizon scales, curvature fluctuations may be generated even if they are initially vanishing;
- examples of the latter phenomenon were provided both analytically and numerically.

As far as applications are concerned, two different situations may arise. In the first case the bulk viscosity is absent from the background, but its inhomogeneities may affect the evolution of the fluctuations with wavelengths larger than the Hubble radius. In the second case, the bulk viscosity does contribute to the background. It has been shown that situations can be envisaged where the contribution of the bulk viscosity coefficient becomes subleading after the decay of the viscous fluid of the mixture. In this case, the curvature fluctuations for length scales larger than the Hubble radius are determined by the interplay of the fluctuating viscosity and of the inhomogeneous decay rate. The final asymptotic value of the curvature fluctuations has been computed in specific numerical examples, where, for instance, the decay products are in the form of a radiation fluid.

Appendix: vector modes

For completeness, some results concerning the evolution of vector modes in a mixture of viscous interacting fluids are reported in the present appendix. They are not central to the present analysis, but are logically connected to the considerations presented so far. In fact, one may wonder if effects similar to the ones discussed for the scalar modes may also arise in the case of vector modes. Consider then the vector fluctuations of the four-dimensional metric (3.4). They are parametrized by two (solenoidal) three-dimensional vectors Q_i and W_i which have, overall, three independent components:

$$\begin{aligned}\delta_v g_{0i} &= -a^2 Q_i, & \delta_v g^{0i} &= -\frac{Q^i}{a^2}, \\ \delta_v g_{ij} &= a^2(\partial_i W_j + \partial_j W_i), & \delta_v g^{ij} &= -\frac{1}{a^2}(\partial^i W^j + \partial^j W^i),\end{aligned}\tag{A.1}$$

where δ_v denotes the vector fluctuation of the various entries of the perturbed metric. It is possible to select a gauge where $\delta_v g_{ij}$ is vanishing. This choice amounts to fixing two degrees of freedom of the perturbed metric. The vector fluctuations of the Einstein equations as well as the vector fluctuations of the equations describing the energy-momentum exchange between different fluids can be written as

$$\delta_v \mathcal{G}_\mu^\nu = 8\pi G \delta_v \mathcal{T}_\mu^\nu, \tag{A.2}$$

$$\nabla_\mu \delta_v \mathcal{T}_a^{\mu\nu} = -\bar{\Gamma} \delta_v g^{\nu\alpha} \bar{u}_\alpha (p_a + \rho_a) - \bar{\Gamma} \bar{g}^{\nu\alpha} \delta_v u_\alpha (p_a + \rho_a), \tag{A.3}$$

$$\nabla_\mu \delta_v \mathcal{T}_b^{\mu\nu} = \bar{\Gamma} \delta_v g^{\nu\alpha} \bar{u}_\alpha (p_a + \rho_a) + \bar{\Gamma} \bar{g}^{\nu\alpha} \delta_v u_\alpha (p_a + \rho_a), \tag{A.4}$$

with the same notation as used in Eqs. (1.1), (1.2) and (2.4), but with the difference that, here, vector fluctuations are considered.

Using the perturbed metric (A.1) and recalling that $\bar{u}_0 \delta_v u^i = \mathcal{V}^i$, the (0i) and (ij) components of Eq. (A.2) imply:

$$\nabla^2 Q_i = -16\pi G(\rho + \mathcal{P})a^2 \mathcal{V}_i, \tag{A.5}$$

$$Q'_i + 2\mathcal{H}Q_i = 0. \tag{A.6}$$

Equations (A.3) and (A.4) lead, instead, to the following pair of equations:

$$[\mathcal{V}_i^{(a)}(\rho_a + \mathcal{P}_a)]' + 4\mathcal{H}[\mathcal{V}_i^{(a)}(\rho_a + \mathcal{P}_a)] = -a\bar{\Gamma}(\rho_a + p_a)\mathcal{V}_i, \tag{A.7}$$

$$[\mathcal{V}_i^{(b)}(\rho_b + \mathcal{P}_b)]' + 4\mathcal{H}[\mathcal{V}_i^{(b)}(\rho_b + \mathcal{P}_b)] = a\bar{\Gamma}(\rho_a + p_a)\mathcal{V}_i. \tag{A.8}$$

Considerations similar to the ones reported in Eqs. (3.42), (3.43) and (3.45) lead to the evolution equation of the total velocity field $\mathcal{V}_i$, i.e.

$$\begin{aligned}[\mathcal{V}_i(\rho_a + \mathcal{P}_a)]' + 4\mathcal{H}[\mathcal{V}_i(\rho_a + \mathcal{P}_a)] &= 0, \\ (\rho + \mathcal{P})\mathcal{V}_i &= (\rho_a + \mathcal{P}_a)\mathcal{V}_i^{(a)} + (\rho_b + \mathcal{P}_b)\mathcal{V}_i^{(b)}.\end{aligned}\tag{A.9}$$

From Eqs. (A.5)–(A.8) it can be easily argued that the spatial fluctuations of the bulk viscosity coefficient do not contribute, as expected, to the evolution of the vector fluctuations of the geometry; the situation is then very similar to the one discussed in the inviscid case in a number of studies that appeared in the past [55, 56] as well as more recently [57, 58, 59, 60]. The difference is, of course, that in the inviscid case the evolution equations of the background are different from those where a homogeneous bulk viscosity coefficient is included. Finally, always for completeness, we should mention that the tensor modes, in some classes of bulk viscous solution, have been analysed in [61].
